Scientists have developed a new biotechnology process that turns waste resources and renewable energy into edible proteins. The two-stage system makes biomass with a protein content of 40–50%. The first stage uses bacteria to convert hydrogen and carbon dioxide into acetate through a carbon-fixing reaction. A culture of baker’s yeast in a second bioreactor converts the acetate along with ammonia and oxygen into edible protein. The recycled ammonia could come from industrial waste streams.

Other microbial protein-generating processes already exist but must be fuelled by sugar, so rely on agriculture. Using renewable electricity to split water to supply the hydrogen and oxygen could give the system a low-carbon footprint.
Sustainable method for producing proteins

Scientists have developed a new biotechnology process that turns waste resources and renewable energy into edible proteins. The two-stage system makes biomass with a protein content of 40–50%. The first stage uses bacteria to convert hydrogen and carbon dioxide into acetate through a carbon-fixing reaction. A culture of baker’s yeast in a second bioreactor converts the acetate along with ammonia and oxygen into edible protein. The recycled ammonia could come from industrial waste streams.

Other microbial protein-generating processes already exist but must be fuelled by sugar, so rely on agriculture. Using renewable electricity to split water to supply the hydrogen and oxygen could give the system a low-carbon footprint.

1. Write an equation for the splitting of water into hydrogen and oxygen.
2. Define the term ‘carbon footprint’.
3. Explain why this process could be sustainable.
