

## Fact sheet: ionic bonding dot and cross diagrams

When a **metal** and a **non-metal** react, the metal atom loses electrons to become a **positively charged ion** and the non-metal atom gains electrons to become a **negatively charged ion**. An **ionic bond** is the strong electrostatic force of attraction between the metal ion and the non-metal ion due to their opposite charges.

A dot and cross diagram is one way to model the transfer of electrons that occurs during this process.

**Did you know ...?** The **group number** on the periodic table tells you how many electrons there are in the outer shell of the atom. You can use this to work out the **charge** of the ion.

### Draw a dot and cross diagram for magnesium oxide

**Magnesium is a metal** in group two of the periodic table, so will form a  $2^+$  ion.

**Oxygen is a non-metal** in group six of the periodic table, so will form a  $2^-$  ion.

1. While you are learning how to draw dot and cross diagrams it's useful to start with something you are already familiar with: **electron configuration diagrams** (see [rsc.li/2WHSi4F](https://rsc.li/2WHSi4F) if you need a reminder). Draw the electron configuration diagrams for each atom in the compound.
2. Look at the number of electrons on the outer shell of each atom. Magnesium has two, oxygen has six. Swap the crosses for dots in one of your diagrams. You don't need to put a circle around the symbol for the nucleus.
3. During **ionic bonding** the atoms form ions by **gaining or losing electrons** to obtain electron configurations with a full outer shell. Magnesium loses two electrons and oxygen gains two electrons. This leaves an  $\text{Mg}^{2+}$  ion and an  $\text{O}^{2-}$  ion.
4. Draw a square bracket around each ion. Magnesium now has an empty third shell so there is no need to draw a third shell.
5. Add the **charge** outside the brackets at the top right corner. Write the size of the charge first, followed by the plus or minus.

#### Did you know ...?

- The **charge** is distributed throughout the ion, the square brackets denote this.
- In an ionic compound the metal ion doesn't just form a bond with the ion it donated electrons to. It forms strong ionic bonds with any ions of opposite charge that fit close enough to it in the **ionic lattice**.
- Magnesium oxide is not soluble in water because the attraction between the **polar water molecules** and the ions is not strong enough to break the ionic bonds between the magnesium and oxygen ions.

## Drawing more complex ionic compounds

In magnesium oxide, the charges on the metal and non-metal ions are **equal and opposite**. What happens when the charges on the ions are **not** equal in magnitude? In aluminium oxide the charge on the positive metal ions is  $3^+$  while the charge on the negative oxide ions is  $2^-$ . The table shows some different ways to draw aluminium oxide ( $\text{Al}_2\text{O}_3$ ).

Variation	Diagram	Details
1		Draw the two positive aluminium ions on the left and the three negative oxygen ions on the right. The number of ions indicates the ratio of aluminium to oxygen.
2		This diagram looks more like the chemical symbol for the compound $\text{Al}_2\text{O}_3$ .
3		The large numbers in this diagram are multipliers. They mean that there are two aluminium ions for every three oxygen ions.
